13. ABSTRACT ***(Maximum 200 Words)***

The changes in the gene program of neoplastic cells that regulate the expression of an invasive phenotype are largely undefined. Direct comparisons of the gene expression profile displayed in normal and carcinomatous breast tissues have provided insights into the mechanisms underlying tumor progression. However, attempts to identify the gene products differentially expressed during invasion *in vivo* have been hampered by the fact that only a small percentage of the cells recovered from a tumor mass are actively engaged in invasive behavior at the time of isolation. Because tissue remodeling induced during mammary gland involution bears homology to early stages of carcinogenesis, the involuting mammary gland may be used to identify genes that control matrix turnover in cancerous states. To this end, we propose to *i) screen involuting versus resting mouse mammary glands by oligonucleotide microarray for differentially expressed gene products associated with matrix remodeling, ii) evaluate potential role of differentially expressed gene products in regulating cell invasion in vitro and/or in vivo and iii) evaluate role of differentially expressed gene products in regulating breast cancer cell invasion.*

I. INTRODUCTION

Current evidence suggests that breast carcinoma cells invade local tissues and metastasize by i) altering their cell-cell and cell-matrix interactions, ii) displaying an aberrant motile phenotype, and iii) either synthesizing, or inducing the synthesis of, proteolytic enzymes that degrade the structural barriers established by the extracellular matrix[1-3]. The complex changes in the gene program of neoplastic cells that regulate the expression of this phenotype are largely undefined, but increased interest has focused on identifying those genes that are specifically overexpressed in human breast cancer[(e.g., 3-10)]. Such information not only provides new insights into the cellular factors that control tissue-invasive behavior, but may also lead to improvements in patient diagnosis and to the more rational design of therapeutic interventions[3-10]. Consistent with this rationale, direct comparisons of the gene expression profile displayed in normal versus neoplastic breast cancer cell lines, or normal and carcinomatous breast tissues, have provided a number of novel insights into the mechanisms and processes underlying tumor progression[6-11]. Interestingly, despite the power of the analytical techniques employed for these purposes, the number of differentially expressed genes identified thus far are - at first glance - perplexingly small, despite the striking changes known to occur in cellular behavior[(e.g., 7,8)]. However, analyses of breast cancer cell lines grown *in vitro* or static tumor masses recovered from *in vivo* sites of disease may be problematic. First, comparisons between normal and neoplastic breast cancer cell lines grown atop plastic substrata *in vitro* will not recapitulate the complex interactions known to occur across the carcinoma-mesenchymal cell axis *in vivo*[1,2]. Indeed, many of the most interesting gene products that have been associated with the expression of tissue-invasive phenotypes in breast cancer tissue are synthesized by surrounding stromal cells rather than the tumor itself[2,3,10]. Secondly, while the gene expression patterns identified in tissues recovered from *in vivo* sites clearly circumvent the limitations inherent in the *in vitro* studies, only a small percentage of the cells recovered from a tumor mass at a single, fixed time point would be expected to be actively engaged in invasive behavior. Given the many similarities between developmental/tissue repair processes and malignant growth (re; the ability of cancer cells inappropriately recapitulate developmental programs associated with epithelial-mesenchymal cell transitions or repair programs associated with wound healing[12,13]), we have considered the possibility that the *in situ* induction of a synchronous matrix remodeling program in normal tissues would allow for the more efficient isolation of those gene products critical to cancer cell invasion. Indeed, recent studies have demonstrated that gene expression patterns associated with the tissue remodeling program induced during the involution of the normal lactating mammary gland bear considerable overlap with those detected in the early stages of carcinogenesis (e.g., stromeylsin-1, stromeylsin-3, urokinase-type plasminogen activator, tissue inhibitor of metalloproteinases[14-16]). Hence, we propose to use the involuting mammary gland explant model as a means to rapidly enrich for, and identify, the subset of genes that control the disassembly of the extracellular matrix in cancerous states. Furthermore, by selectively identifying the subset of gene products that regulate invasion of breast cancer cells, new diagnostics as well as novel targets for therapeutic intervention can be rapidly identified.

II. BODY

In the original proposal, we intended to generate cDNA libraries from control versus involuting mammary gland explants. However, the high rate of cell apoptosis in control glands precluded

analysis and emphasis was shifted to analyses of gene expression patterns in tissues recovered from lactating versus involuting glands *in vivo* by oligonucleotide array (see approved "Revised Statement of Work"). Each of the proposed aims have now been completed as described below.

Task 1. Screen involuting versus resting (i.e., lactating) mammary glands by oligonucleotide array for differentially expressed gene products associated with matrix remodeling.

a. Documentation of involution program in mammary explants. To demonstrate that an involution program was successfully engaged in mammary gland tissue, glands were excised from lactating (day 10) or involuting glands (day 3 post-weaning). Tissue sections were then processed for H and E staining, apoptosis (as assessed by TUNEL staining) or for the dissolution of the subepithelial basement membrane by immunofluorescence (as assessed by staining for type IV collagen or laminin). As shown in Figure 1, the milk-engorged ductal system of lactating mice rapidly collapsed 3 days post-weaning. Coincident with this event, an increase in apoptosis was noted which paralleled a major loss and/or fragmenting of basement membrane-associated type IV collagen or laminin (Fig. 1). As the matrix-degrading involution program had been successfully engaged, tissues from the mice were collected and subjected to oligonucleotide array analysis as described below.

b. Collection mRNA and performance of oligonucleotide microarray analysis. In three experiments, RNA was isolated from glands with a Qiagen RNassay mini-kit and cRNA prepared for hybridization as described[17,18]. Oligonucleotide arrays (Gene Chip, Affymetrix) representing a total of 30,000 EST cluster sequences and/or full-length genes were used for hybridization according to the manufacturer's instructions. Arrays were then scanned using an Affymetrix confocal scanner and analyzed using Gene Chip 3.0 Software (Affymetrix). Expression data from the Affymetrix arrays were analyzed using a statistically based analysis methodology that estimates expression levels and provides confidence intervals for these estimates. It also allows for the normalization of array-based expression data to control for variations due to non-biological factors such as array-to-array variability, and variations in sample quality. For each gene, the presence or absence of a transcript was determined by testing the Null hypothesis. Briefly, the arrays included a set of probes derived from non-eukaryotic ("foreign") organisms (e.g., bacterial and bacteriophage sequences) which were defined as the "null set". This null set thus defines the intensity of nonspecific background/cross-hybridization. This null intensity distribution is modeled by a parametric statistical distribution. Since intensity is a positive random variable, this null distribution is modeled by either a Gamma or a Weibull class distribution. Once the parametric null distribution is determined, we computed the p-value for the hypothesis that the observed hybridization intensity values are also a random sample from the null distribution. Target genes with low p-values (i.e., not likely to have come from the same distribution as the null genes) are classified as present. The p-value provides a continuous measure of the confidence in the presence of a gene in the target sample. We also include a mathematical method to standardize the gene-expression levels between different samples, based on exogenous gene spikes, added at known concentrations, that constitute a calibration set[18]. Genes scored as "positive" (i.e., induced) in involuting tissues were i) more highly expressed in each of 3 independently performed experiments and ii) expressed at levels ≥ 2.5 than those detected in lactating glands in at least 2 of the 3 experiments.

Following analysis of the approximately 100 genes whose expression was upregulated as defined, a series of proteolytic enzymes were identified (Appendix I). In the matrix metalloproteinase family, stromelysin-1 was the only upregulated member whose expression reached significance (Appendix I). However, the membrane-anchored metalloproteinase, MT1-MMP, was also identified though its expression level did not increase by the requisite 2.5-fold in 2/3 samples. However, given the positive trend, samples from involuting tissues were examined by RT-PCR at both 3 and 5 days post-weaning. Significantly, MT1-MMP mRNA was dramatically upregulated at the latter time point (Fig. 2). In addition, message levels for three matrix-destructive cathepsins were also found to be upregulated during involution, i.e., the aspartyl proteinase cathepsin D, and the cysteinyl proteinases, cathepsins L and S.

Table I
Fold-Increase in Gene Expression

	EXP #1	EXP #2	EXP #3
cathepsin D	4.7	3.9	2.3
cathepsin L	4.1	2.9	1.8
cathepsin S	7.4	6.2	2.3

<u>Task 2.</u> Evaluate the potential role of differentially expressed gene products in regulating cell invasion in vitro and/or in vivo.

With regard to the MMPs, both stromelysin-1 and MT1-MMP are expressed in breast cancer[19,20]. Thus, we sought to determine whether either of these enzymes might serve as basement membrane-degrading enzymes. To this end, we developed a model system wherein an immortalized epithelial cell line deposits an intact basement membrane *in vitro* (containing type IV collagen, laminin and heparan sulfate proteoglycan; data not shown) atop a dense layer of type I collagen (Fig. 3). Following lysis of the overlying epithelium, COS-1 cells that have been engineered to overexpress human stromelysin-1 were then allowed to adhere to the denuded basement membrane. Following a 5 d incubation period, the basement membrane retained its normal structure as assessed by transmission electron microscopy (Fig. 4). However, in marked contrast, cells transfected with MT1-MMP not only rapidly degraded the underlying substratum, but also conferred the recipient cells with invasive activity (Fig. 5). While MT1-MMP could conceivably mediate basement membrane degradation directly, the proteinase can also process the MMP zymogen, gelatinase A (or MMP-2), to its active form[21]. Further, gelatinase A has been posited to serve as a basement membrane degrading enzyme itself[22]. However, COS-1 cells do not express gelatinase A and the experiments described above were performed in the absence of exogenous gelatinase A (i.e., serum contains gelatinase A, but this can be removed by gelatin-affinity chromatography)[21]. Nonetheless, to rule out a role for gelatinase A directly, COS-1 cells were stably transfected with gelatinase A and cultured atop the denuded basement membrane as described. While no change in basement membrane structure was noted (data not shown), the cells only secreted gelatinase A in its latent form (see below). To test the ability of active gelatinase A to exert proteolytic activity in this system, a chimeric enzyme was designed wherein a basic recognition motif (RXKR, where R = Arg, X = any amino acid, K = Lys) for the proprotein convertase, furin, was inserted directly upstream of the catalytic domain of gelatinase A between N^{109} and Y^{110} (we described this general approach previously for other MMPs in ref.

23). In this manner, progelatinase is cleaved within the *trans*-Golgi network to a fully active form prior to secretion. Indeed, as shown in Figure 6, supernatants of transfected cells released active gelatinase A as assessed by gelatin zymography. Nonetheless, cells overexpressing active gelatinase A did not display basement membrane-degrading activity (Fig. 6). Likewise, the closely related gelatinase, MMP-9, was also unable to degrade the underlying basement membrane when expressed in its fully active form (the basic recognition motif was inserted between R^{106} and F^{107}; Fig. 6). Thus, only MT1-MMP, an MMP upregulated during the involution cycle, arms expressing cells with the ability to degrade the basement membrane construct used in these studies. Nonetheless, as the basement membrane was generated *in vitro*, concerns could be raised that basement membranes assembled *in vivo* display unique properties relative to their susceptibility to degradation. Consequently, we have extended these studies to analyze the ability of MT1-MMP to degrade basement membrane recovered from animal tissues. As shown in Figure 6, an intact basement membrane is located beneath the mesothelial cell layer of the peritoneum, Hence, resident cells were lysed by freeze-thawing and the denuded peritoneal basement membrane overlaid with MT1-MMP expressing COS-1 cells. As predicted, the MT1-MMP transfected cells displayed a proteolytic activity similar, if not identical, to that observed with the "*in vitro*" basement membrane constructs (Fig. 7). Further, the invasive/degradative activity was completely blocked in the presence of the synthetic MMP inhibitor, BB-94 (Fig. 7).

While cathepsin D has been previously associated with human breast cancer and shown to express matrix destructive activity *in vitro*[24,25], roles for cathepsins L and S in regulating extracellular matrix turnover are less clear. Though these enzymes are usually confined to the lysosomal system (they are unstable at neutral pH), we have recently characterized cathepsin L and S as matrix-destructive enzymes in human macrophages[26]. However, whereas macrophages are able to secrete the active enzymes extracellularly into an acidic pericellular environment maintained by H^+-pumps targeted to the plasma membrane, we have been unable to identify other cell types capable of displaying this phenotype[26]. As such, we have been unable to demonstrate the ability of cathepsin L or S to confer degradative activity in transfected COS cells. Given this limitation, we instead attempted to determine whether the involution program in cathepsin L/S-deleted mice was affected. However, these animals did not breed well in our facility which precluded attempts to study the effects of the L/S-deficient state on the involution program. Further, in the absence of direct evidence to support their extracellular secretion from the mammary epithelium (or tumor cells), we would not be able to rule out the possibility that the proteinases were only required for intracellular, lysosomal degradation and not extracellular proteolysis.

<u>Task 3.</u> Evaluate the role of differentially expressed gene products identified in the involution screen to regulate breast cancer invasion.

To determine the ability of MT1-MMP to regulate tumor cell invasion, we first examined the ability of invasion-incompetent MCF-7 cells to penetrate the basement membrane before or after transfection with MT1-MMP. As shown in Figure 8, MCF-7 breast cancer cells seeded atop the basement membrane construct did not display invasive activity as assessed by phase contrast microscopy or in H-E sections. However, following transfection with MT1-MMP (but not stromelysin-1), the cells displayed striking invasive activity (Fig. 8). As human breast cancer tissue expresses MT1-MMP *in vivo*[27], the invasive activity of MT1-MMP-positive tumor cells

were examined (i.e., the MB-231 cell line). Significantly, when those cells were cultured atop the peritoneal basement membrane, the underlying matrix was degraded (as assessed by scanning electron microscopy; Fig. 9). In the presence of recombinant TIMP-2, a potent MT1-MMP inhibitor, degradation and invasion were completely blocked over a 7 d assay period (Fig. 9). In preliminary experiments performed with a neutralizing monoclonal antibody directed against MT1-MMP, invasive activity was likewise inhibited completely. Taken together, these data suggest that MT1-MMP may be the critical proteinase involved in basement membrane degradation and invasion by breast carcinoma cells.

III. KEY RESEARCH ACCOMPLISHMENTS

- Gene program associated with mammary gland involution program characterized.
- Membrane type-1 matrix metalloproteinase identified as key basement membrane degrading enzyme.
- Membrane type-1 matrix metalloproteinase identified as pro-invasive factor for human breast cancer cells and potential target for therapeutic intervention.

IV. REPORTABLE OUTCOMES

- Presentation at Gordon Conference on Matrix Metalloproteinases, 2001.
- New funding obtained to assess role of membrane-type matrix metalloproteinases in breast cancer development from Komen Breast Cancer Foundation.
- Manuscript in preparation, "Regulation of Basement Membrane Invasion by MT1-MMP", Kevin Hotary and Stephen J. Weiss.

VI. CONCLUSIONS

With the identification of suitable mammary gland tissues for isolating gene products differentially expressed during matrix-remodeling events, the model system has been used to identify genes that likely control the disassembly of the matrix during tumor invasion and metastasis. Furthermore, by selectively identifying critical gene products that regulate invasion, new diagnostics as well as novel targets for therapeutic intervention may be identified.

Figure 1. Induction of Mammary Gland Involution Program. Lactating (10 days) or involuting (3 days post-weaning) glands were isolated from wild-type mice and tissues processed for H and E staining and apoptosis (TUNEL) as well as immunostaining for laminin and type IV collagen as described[27]. Lactating glands were milk-engorged and showed no significant apoptosis. In addition, basement membranes were laminin- and type IV collagen- positive. Following 3 days of involution, glandular structures collapsed and apoptotic cells were observed as yellow-green staining. Laminin staining decreased significantly while type IV collagen immunoreactivity decreased coincident with a thickening/blurring of basement membrane structure.

Figure 2. RT-PCR Analysis of MT1-MMP Expression in Mouse Mammary Glands. RNA was isolated from virgin, 10 d lactating, 1 d involuting or 5 d involuting glands. Reverse transcription was performed as described[28]. The arrow at left marks the position of the MT1-MMP standard.

Figure 3. Basement Membranes Synthesized by MDCK Epithelial Cells are Deposited Atop a 3-Dimensional Type I Collagen Gel During a 3 Week Culture Period. In panel A, TEM analysis shows an epithelial cell depositing a ~90 nm thick basement membrane which is more readily observed after the overlying cell layer has been lysed (panel B). Panels C and D are scanning electron micrographs showing the type I collagen gel upon which the intact basement membrane is deposited, respectively.

Figure 4. Basement Membrane-Invasive Potential of Stromelysin-1. Stromelysin-1 transfected cells cultured atop an intact basement membrane (arrows) were unable to confer degradative or invasive activity as visualized by transmission electron microscopy.

Figure 5. MT1-MMP-Dependent Basement Membrane Degradation/Invasion. Control cells did not penetrate the basement membrane as assessed by TEM or SEM analysis following a 5 d incubation period. (upper left and right panels). In contrast, MT1-MMP-transfected cells perforated the BM in representative TEM and SEM samples, respectively. Arrows indicate the position of the basement membrane.

Figure 6. Active MMP-2 or MMP-9 Do Not Confer Basement Membrane-Invasive Activity. COS-1 cells were transfected with MMP-2 or MMP-9 chimeric constructs and supernatants analyzed for MMP activation by gelatin zymography (yellow arrow in left panel depicts position of proenzyme and the red arrow marks the position of the fully active, processed enzyme) or for basement membrane degradation (right side) by scanning electron microscopy.

Figure 7. MT1-MMP-Dependent Degradation of an In Vivo-Generated Basement Membrane. In the upper panel, the ~90 nm thick peritoneal basement membrane is visualized by TEM. In the three lower panels, SEM analysis demonstrates that MT1-MMP-transfected cells, but not control vector transfectants, degraded the underlying basement membrane by a process that was blocked by the synthetic MMP inhibitor, BB-94 (5 μM).

Figure 8. MT1-MMP Regulates Basement Membrane Invasion of Transfected MCF-7 Cells. Wild-type or MT1-MMP-transfected MCF-7 cells were cultured atop a basement membrane construct which overlaid a 3-D type I collagen gel in a Transwell insert as described. Following a 5 d incubation period, invasion by MT1-MMP transfectants was observed by phase contrast microscopy (left panel) or in H and E sections (right panel). The control MCF-7 cells which do not express MT1-MMP, did not display invasive activity.

Figure 9. Basement Membrane Invasion by Human MB-231 Breast Cancer Cells. Peritoneal basement membranes (top panel) were used as a substratum for MB-231 cells during a 5 d incubation period. Cells were then lysed and the underlying basement membrane viewed by scanning electron microscopy. MB-231 cells left large holes in the basement membrane leaving the underlying interstitial matrix exposed (middle panel). Culturing the MB-231 cells atop the basement membrane in the presence of the MMP inhibitor, TIMP-2 (5 μg/ml), left the basement membrane largely intact (bottom panel).
